Abstract: We study the propagation of long periodic waves over semi-buried cylindrical objects in the bottom. We present a combination of laboratory wave tank experiments, with a sandy bottom, and numerical modeling, using a two-dimensional fully nonlinear potential flow model. Experiments provide wave elevation at gages and velocity fields measured around the semi-buried objects, using an Acoustic Doppler Velocimetry (ADV) method. The model is run for the same geometry and wave parameters as in the experiments. A numerical absorbing beach is used to both prevent waves from overturning and specify wave absorption in the model surfzone. Bottom friction in the shoaling region is specified as a corresponding energy loss in the model, by using an absorbing surface pressure. Without the semi-buried cylinder, the comparison between computed and experimental results is quite good for both surface elevation and near bottom velocities, even for waves near the breaking point. Strong asymmetry is observed for the bottom velocities under nonlinear shoaling waves, with respect to the front and rear of the waves, and with respect to wave elevations from mean water level. These velocities are compared to standard predcitions of linear wave theory and differences are discussed. With the cylinder, the agreement of computed and measured velocities close to the cylinder is also good, except, just in front and behind the cylinder, likely due to vortex shedding. The model can thus be used to accurately provide background wave fields around the buried object, say, at one diameter away. Based on these, more refined hydrodynamic and sediment transport modeling can be performed in future studies.

Keywords: Nonlinear nearshore wave transformations, wave shoaling and breaking, numerical wave tank,

boundary element method, sandy bottom, sediment transport.

Introduction

The main motivation for this work is the recent interest of the U.S. Navy for the behavior, and possible scour/burial, of large cylindrical objects (mines) on the ocean bottom, in a coastal environment where nonlinear waves play the dominant role. Another, more fundamental, motivation is to gain insight into the relationship between sediment motion and its forcing due to nonlinear wave flows around bottom obstacles.

The behavior of solid objects, such as mines, located on or partly within sandy bottom, in shallow water coastal areas, is strongly affected by the near bottom velocity and pressure induced by shoaling water waves. In turn, such objects also strongly affect the near bed wave flow, within a short distance, usually making velocities increase near the objects and thus increasing local sediment transport rates (Voropayev et al., 2003a). Predicting the objects' burial or scouring thus requires a detailed analysis of near bottom wave fields around the object. Long shoaling waves (swells) approaching breaking in sandy coastal areas usually become locally two-dimensional (2D) (in a vertical plane), due to refraction. Such waves, when propagating over sandy bottom in shallow water also usually induce the formation of ripples. As waves shoal up, their increasing nonlinearity leads to both up-down and front-rear asymmetry of the wave profile, and to a corresponding asymmetry of the near bottom velocities. Such asymmetry in wave forcing, in turn induces an asymmetry of the induced sediment transport, causing ripples to migrate up slope (Vittori and Blondeaux, 1990; Blondeaux et al., 2000; Voropayev et al. 2003b). Numerical modeling of such phenomena, particularly in the presence of objects on the bottom is a very challenging problem, for which little has been reported (Kan et al., 2001). More experimental work has been reported, mostly for 2D configurations, such as waves propagating over pipelines (Cevik and Yuksel, 1999). Voropayev et al. (2003a) studied the burial/scouring of short cylindrical horizontal objects, under a shoaling swell, a case for which sediment transport is three-dimensional (3D), but the forcing flow, except close to the object, is essentially 2D.

The present modeling work was performed in parallel with the latter experimental work. A Numerical Wave Tank (NWT) solving fully nonlinear potential flow equations was used (Grilli et al., 1989; Grilli and Subramanya, 1996; Grilli and Horrillo, 1997a). This model has been extensively experimentally validated,

2

and shown to accurately simulate shoaling of waves over mildly sloping beaches (including barred beaches), up to the breaking point (Grilli et al., 1994, 1997, Grilli and Horrillo, 1997b,1999). Here, the NWT is set-up and run for the same geometry and wave parameters as in experiments performed at Arizona State University (ASU; see Voropayev et al. 2003a,b, for details of the experimental set-up and results). Experiments provide wave elevation at gages and velocities measured at various sections along the slope, and around semi-buried cylinders, using an Acoustic Doppler Velocimetry (ADV) method.

In this work, both wave elevation at numerical gages, and velocity and pressure fields in the presence of cylindrical objects, are computed in the NWT. Numerical results are compared with experiments and differences are discussed. In the following, we briefly present model equations and numerical methods. We then give detailed results of computations and make the comparisons with experiments.

Numerical Wave Tank

Governing equations and boundary conditions

Equations for the two-dimensional NWT are briefly presented in the following (see Grilli et al., 1989, Grilli and Subramanya, 1996, and Grilli and Horrillo, 1997a, for details). The velocity potential $\phi(\boldsymbol{x}, t)$ is used to describe inviscid irrotational flows in the vertical plane (x, z) and the velocity is defined by, $\boldsymbol{u} = \nabla \phi = (u, w)$. Continuity equation in the fluid domain $\Omega(t)$ with boundary $\Gamma(t)$ is Laplace's equation for the potential (Fig. 1),

$$\nabla^2 \phi = 0 \qquad\qquad\qquad \text{in } \Omega(t) \qquad\qquad\qquad (1)$$

On the free surface Γ_f, ϕ satisfies the kinematic and dynamic boundary conditions,

$$\frac{D \boldsymbol{R}}{D t} = (\frac{\partial}{\partial t} + \boldsymbol{u} \cdot \nabla) \boldsymbol{R} = \boldsymbol{u} = \nabla \phi \qquad\qquad \text{on } \Gamma_f(t) \qquad\qquad (2)$$

$$\frac{D\phi}{Dt} = -gz + \frac{1}{2} \nabla \phi \cdot \nabla \phi - \frac{p_f}{\rho} \qquad\qquad \text{on } \Gamma_f(t) \qquad\qquad (3)$$

respectively, with $\boldsymbol{R}$, the position vector on the free surface, g the gravitational acceleration, z the vertical coordinate, p_f the free surface pressure, and ρ the water density. Along the bottom boundary Γ_b, a no-flow

condition is prescribed as,

$$\overline{\frac{\partial \phi}{\partial n}} = 0 \qquad\qquad \text{on } \Gamma_b \qquad\qquad (4)$$

where the overline denotes specified values.

Various methods have been used for wave generation in this NWT. Here, periodic waves are generated on boundary Γ_w as in the experiments, using a solid piston wavemaker moving according to a simple sinusoidal motion, $x = x_w(t)$. thus, we have,

$$\overline{x_w} = \frac{S_o}{2} \sin{(\omega t)} \ ; \ \overline{\frac{\partial \phi}{\partial n}} = -\frac{\mathrm{d}x_w}{\mathrm{d}t} \qquad \text{on } \Gamma_w \qquad\qquad (5)$$

where S_o and ω denote wavemaker stroke and circular frequency, respectively, and the time derivative follows the wavemaker motion. Note, in the computations, the piston motion is ramped-up over three wave periods, by modulating the stroke using a tanh function of time. See references for details.

Wave energy absorption

Following Grilli and Horrillo (1997) an absorbing beach (AB) is used in the NWT, for $x \geq x_a$ (Fig. 1), to both prevent waves from overturning and breaking at the top of the slope (which would interrupt computations) and to dissipate the energy of incident waves. In the AB, an external absorbing pressure $p_f = p_a$ is specified on the free surface, by way of the dynamic free surface condition (3) (with $z = \eta$), to create a negative work and absorb wave energy. Additional wave reduction is induced by causing waves to de-shoal, using a bottom geometry within the AB somewhat similar to a natural bar, with a depth increasing from $h(x_r)$ to h_1 (Fig. 1).

Here, the AB absorbing pressure is specified proportional to the normal particle velocity on the free surface,

$$p_a(x, \eta, t) = v_a(x) \frac{\partial \phi}{\partial n}(\eta(x, t)) \qquad\qquad (6)$$

where v_a is the beach absorption function. This function is first ramped-up from 0 to v_{ao} and then maintained

constant over the AB. More specifically, we have,

$$v_a(x) = v_{ao} \, \rho \sqrt{gh_1} \, f(x) \tag{7}$$

where v_{ao} is a non-dimensional beach absorption coefficient, and $f(x)$ follows a tanh variation for $x_a \leq x \leq x_r$, and $f(x) = 1$ for $x_r < x \leq x_p$.

Following Grilli and Horrillo (1997), an absorbing piston (AP) is also specified at the extremity of the AB, for $x = x_p$. This AP moves proportionally to the hydrodynamic pressure force caused by waves, calculated as a function of time in the NWT (see references for details). Grilli and Horrillo (1997) showed that the combination AB/AP effectively absorbs incident wave energy in the NWT, to within any specified small fraction.

In the present work, we wish to simulate wave shoaling over a rippled sandy bed. Although, for short distances of propagation over a smooth bottom, wave damping due to bottom friction is quite small and usually neglected in numerical models, in the present case, bed roughness due to ripples may induce more significant wave damping. Thus, bottom friction should be accounted for in the NWT. Since no mechanism is available to dissipate energy in potential flow models, the same method as used for the AB is used to specify energy dissipation due to bottom friction over the shoaling region of the NWT, which has the rippled sandy bed, i.e., for $x_w < x \leq x_a$ (Fig. 1). More details regarding this new addition to the NWT are given below.

In turbulent conditions, the wave induced shear stress in the tangential direction s to the bottom, is given by (e.g., Fredsoe and Deigaard, 1994),

$$\tau_{bs} = \frac{1}{2} \rho \, f_{wb} \, |u_{bs}| \, u_{bs} \quad \text{with} \quad f_{wb} = c_1 \left(\frac{\zeta_{bs}}{k_l} \right)^{c_2} \tag{8}$$

where, $u_{bs} = -\partial\phi/\partial s$ (positive onshore; curvilinear abscissa s is postive clockwise) is the tangential velocity calculated on the bottom, $c_1 \simeq 0.04$ and $c_2 \simeq -0.25$ are constant coefficients, $k_l \simeq 2.5 \, d_{50}$ is the bed roughness, with d_{50} the median diameter for the sediment, and ζ_{bs} is the maximum excursion of water particles on the bottom.

The energy flux dissipated by bottom friction over the shoaling zone is given by the work of the shear

stress per unit time,

$$E_{fb} = \frac{1}{2} \rho \int_{x_w}^{x_r} f_{wb} |u_{bs}| u_{bs}^2 \, \mathrm{d}s \tag{9}$$

The absorbing pressure is defined on the free surface such as to mimic the bottom shear stress variation as,

$$p_b = \nu_{bo} \, \rho \, f_{wf} \, u_{bs}^2 \, \mathrm{sign}(\frac{\partial \phi}{\partial n}) \; ; \text{on } \Gamma_f, \, x_w < x \le x_r \tag{10}$$

where $u_{bs} = \partial \phi / \partial s$ is now the tangential velocity calculated on the free surface, and f_{wf} is interpolated, for any given x, from values of f_{wb} calculated on the bottom. The nominal energy flux produced by this pressure over the free surface is (when $\nu_{bo} = 1$),

$$E_{fs} = \rho \int_{x_w}^{x_r} f_{wf} \, u_{bs}^2 \, |\frac{\partial \phi}{\partial n}| \, \mathrm{d}s \tag{11}$$

By specifying that the dissipated energy flux E_{fb} and that produced by the absorbing pressure are equal, we find the time dependent non-dimensional coefficient, $\nu_{bo} = E_{fd}/E_{fs}$, with which we can calculate the absorbing pressure over the shoaling zone using Eq. (10), and specify it in the NWT dynamic free surface boundary condition (3), as $p_f = p_b$.

For linear periodic waves of frequency ω, the maximum particle excursion is, $\zeta_{bs} = u_{bs}^{max}/\omega$, where u_{bs}^{max} denotes the maximum tangential velocity on the bottom given by,

$$u_{bs}^{max} = \frac{gk \, H}{2 \, \omega \, \cos \theta} \frac{1}{\cosh kh} \tag{12}$$

where H is wave height, $\theta = \tan^{-1} S$ is the bottom slope angle (Fig. 1), $h(x)$ is the local depth, and k is the wavenumber given as a function of h and ω by the linear dispersion relationship,

$$\frac{\omega^2}{g} = k \, \tanh kh \tag{13}$$

Applying linear shoaling wave theory and using Eqs. (12) and (13), we find,

$$\zeta_{bs} = \frac{H_o}{2 \, \cos \theta \, \sinh kh} \sqrt{\frac{m_o}{m}} \tag{14}$$

with,

$$m = \tanh kh \left(1 + \frac{2kh}{\sinh 2kh} \right) \tag{15}$$

6

as a function of kh, and $m_o = m(k_o h_o)$ for the incident wave conditions in depth h_o, with H_o the incident wave height, estimated using linear wavemaker theory for a piston wavemaker as,

$$H_o = 2S_o \frac{\cosh 2kh \ - \ 1}{2kh \ + \ \sinh 2kh} \tag{16}$$

In the NWT, linear wave theory Eqs. (13) to (16) are used to initialize $\zeta_{bs}(x)$ values in Eq. (8) and (9). For nonlinear waves, such as generated in the NWT, values of both bottom velocity and maximum excursion are calculated, as a function of time, based on local wave parameters. Hence, after an initial ramp-up period, ζ_{bs} values are updated at each time step using computed values of u_{bs}^{max}.

Numerical model

In the NWT, Eq. (1) is transformed into a Boundary Integral Equation (BIE), using Green's 2nd identity, and solved by a Boundary Element Method (BEM). The BIE is expressed for N discretization nodes on the boundary, and M higher-order elements are defined to interpolate in between discretization nodes. In the present applications, quadratic isoparametric elements are used on lateral and bottom boundaries, and cubic elements ensuring continuity of the boundary slope are used on the free surface. In these elements, referred to as Mid Cubic Interpolation (MII) elements, both geometry and field variables are interpolated between each pair of nodes, using the mid-section of a four-node "sliding" isoparametric element. Detailed expressions of BEM integrals (regular, singular, quasi-singular) are given in Grilli and Subramanya (1996), for both isoparametric and MII elements.

Free surface boundary conditions (2) and (3) are time integrated based on two second-order Taylor series expansions expressed in terms of a time step Δt and of the Lagrangian time derivative, D/Dt, for ϕ and $\mathbf{R}$. First-order coefficients in the series correspond to free surface conditions (2) and (3), in which ϕ and $\partial \phi / \partial n$ are obtained from the BEM solution of the BIE for $(\phi, \partial \phi / \partial n)$ at time t. Second-order coefficients are expressed as D/Dt of Eqs. (2) and (3), and are calculated using the solution of a second BIE for $(\partial \phi / \partial t, \partial^2 \phi / \partial t \partial n)$, for which boundary conditions are obtained from the solution of the first BIE and the time derivative of Eqs. (3) to (5). Detailed expressions for the Taylor series can be found in Grilli et al. (1989).

7

At each time step, global accuracy of computations is verified by computing errors in total volume and energy for the generated wave train. Earlier work showed that these errors are function of both the size (i.e., distance between nodes) and the degree (i.e., quadratic, cubic,...) of boundary elements used in the spatial discretization, and of the size of the selected time step. Thus, Grilli and Subramanya (1996) adaptively selected the optimal time step, based on a mesh Courant number $\mathcal{C}_o(t)$ and, for MII elements, and showed that the optimum value of $\mathcal{C}_o$ was about 0.45. This value is used in the present applications.

In computations involving finite amplitude waves, mean drift currents occur ("Stokes drift"), which continuously move free surface discretization nodes/Lagrangian markers away from the wavemaker into the NWT. Grilli and Subramanya (1996) developed regridding methods in which nodes can be redistributed at constant arclength intervals over specified regions of the free surface. This method is used here over the whole free surface, every 10 time steps.

Applications

Modeling of experimental tank in NWT

Fig. 1 shows a sketch of the computational domain defined in the NWT to simulate laboratory experiments in ASU's wave tank. A piston wavemaker is specified on the leftward boundary at $x = x_w$, with initial (mean position) at $x = 0$. The intial water depth is $h_o = 1.05$ m. On the bottom, ASU's tank has a 0.21 m thick layer of fine sand with $d_{50} = 0.06$ cm (located between the large chained lines on Fig. 1), starting at $x = 1.22$ m, with a 1:6 slope, and followed, at $x = 3.05$ m, by a 1:24 slope.

As detailed above, in the NWT, the surfzone is modeled by an AB, starting, here, at $x_a = 12.80$ m. In the AB, the sloping bottom is interrupted at $x_r = 16.5$ m, slightly before the breaking point in the experiments and, for $x > x_r$, the depth is gradually increased to $h_1 = 0.5$ m, following a gentle tanh variation. The AB non-dimensional absorption coefficient ν_{ao} is ramped up from 0 to 0.4, from x_a to x_r, and then maintained constant.

In the laboratory tank, the sandy bottom is rectified before each new experiment. During experiments, it is observed that sand ripples rapidly form and migrate onshore under wave action. Measurements are made

after the bed shape is fully developed. In the NWT, we did not represent the exact shape of ripples nor their motion. The observed ripples were quite small in amplitude and their effect on the overall wave field, computed at any time, could be simply represented by an enhanced energy dissipation due to bottom friction. Moreover, because the time scale of evolution of bottom morphology features is much larger (minutes to hours) than that of the hydrodynamic wave forcing (seconds), the bottom shape could safely be assumed stationary. Hence, the effect of ripples was only represented.

Some experiments were run in ASU's tank without any bottom obstacles. In other experiments, a circular cylinder of radius $r = 0.084$ m, and length equal to almost the tank width, was placed on the bottom at $x = 11.58$ m, hereafter referred to as section 18 (or S18; Fig. 1). We model both cases in the NWT, using 342 nodes in the BEM discretization, 149 of which are located on the free surface. With $x_p = 29.60$ m at $t = 0$, the initial element length on the free surface is $\Delta x_o = 0.20$ m. For a Courant number equal to 0.45, the initial time step was $\Delta t_o = 0.034$ s. A total of 3500 time steps are typically run in each of these computations (the CPU time per time step is about 0.75 s on a MAC-G4/500MHz), leading to a maximum simulated time of 75.8 s and an average time step about 0.02s. This also corresponds to about 30 incident wave periods. In the computations, the relative error on mass conservation in the NWT, calculated by integrating the mass flux through the NWT boundary at each time step, is less than $4 \ 10^{-5}$%, and for the total NWT volume, the error is less than 0.45% at the end of the computations. Part of this, however, is due to some water exiting the domain through the AP motion, by way of nonlinear effects.

Calibration and validation of NWT

Laboratory experiments were run with and without the cylindrical bottom obstacle, and measurements of surface elevation and near bottom velocity were taken and (phase) averaged; in the second case this was done when the cylinder was half-buried. We run similar cases in the NWT and found that the cylinder had very little effect on computed phase-averaged wave elevations, even right above the cylinder (Fig. 5). Velocities, however, particularly closer to the cylinder were strongly affected by its presence. Details are given in the following.

Incident wave and surface wave elevations at gages

Calibration of the incident wave in the NWT is carried out using measurements made at gages without the cylinder in place on the bottom, and running computations for a plane sandy slope. All computations are run for a wave period $T = 2\pi/\omega = 2.5$ s (i.e., $\omega = 2.513$ s^{-1}) and an experimental wavemaker stroke $S_o = 0.25$ m. Based on Eq. (16) and using the latter, linear wavemaker theory predicts an incident wave height $H_o = 0.228$ m at the wavemaker. Wave height was measured to $H_o = 0.21$ m in experiments, at the toe of the slope (S3 in Fig. 1). Using the experimental stroke value in the NWT, for wavemaker boundary condition Eq. (5), we find that computed waves are too large at S3. This discrepancy can be explained by noting that there were water leaks between the wavemaker and tank walls and bottom in ASU's experiments, hence, leading to a reduced wavemaking efficiency. Such leaks cannot be prevented for this type of wavemaker and corrections should thus be made. Consequently, we find that measured waves are accurately reproduced at gage S3 in the NWT by reducing the piston stroke to $S_o = 0.21$ m, which leads to a wave height (phase-averaged over 20 periods) $H_o = 0.206$ m.

We specify the surface absorbing pressure in the NWT and calculate v_{bo} as detailed before, using Eqs. (9) and (11), for $x = 1.22$ m to x_r. For the bottom friction coefficient f_{wb} in Eqs. (8) to (11), we used $c_2 = -0.25$. For c_1, however, after running several calibration tests and comparing simulated and measured wave heights at gages S20, S22 and S24 (Fig. 1), we found it necessary to specify a larger value, $c_1 = 0.25$, than the typical value used for a smooth bottom. This is likely due to the effect of ripples, which increase near bottom turbulence through flow separation and, hence, enhance bottom friction effects on waves. Fig. 2 shows energy fluxes E_{fb} and E_{fs} computed as a function of time. We see that the NWT reaches a quasi-steady state for $t > 20$ s. After that time, we find v_{bo} varies between 0.3 and 0.65, with an average value around 0.45. The energy dissipated by bottom friction over each time step, $E_{fb} \Delta t$, was compared to the instantaneous wave kinetic energy computed in the NWT as,

$$E_k = \frac{1}{2}\rho \int_\Gamma \phi \frac{\partial \phi}{\partial n} \, d\Gamma \tag{17}$$

For $t > 20$ s, we find that energy dissipation by bottom friction only represents an average of 0.03% of E_k.

So, despite the rippled bed, energy dissipation by bottom friction is still quite small. NWT results were phase averaged over one wave period, to compare them with laboratory experiments. Due to the initial ramp-up of the wavemaker motion and delays for waves to reach gages S18 to S24, due to propagation over the slope, the first 5-10 computed periods are usually excluded from these phase averaging. Hence, in computations, phase averages are typically performed over 20 periods or so, during which waves have reached a quasi-steady state (i.e., from $t = 20$ to 70 s; e.g., Fig. 2). By contrast, in the experiments, time averages were performed over 30-40 wave periods.

Fig. 3 shows instantaneous wave elevations computed at gages S3 to S24 (Fig. 1), for the sandy bottom without the cylindrical obstacle. The increasing wave nonlinearity during shoaling is quite apparent and leads to both increasing up/down and front/rear asymmetry of the wave shape. Fig. 4 shows phase averages of Figs. 3(c) to (e) results, as well as computed minimum and maximum envelopes. Average values are compared to experimental results. The agreement is quite good for results at gages S20 and S22, but less good for S24, particularly for the wave shape near the crest. This is likely due to the use of an empirical AB in the present computations to model these nearly breaking waves. More accurate results for breaker shape and height could be obtained by using the spilling breaker model of Guignard and Grilli (2001). We elected not to tackle such more computationally intensive computations, because they would unecessarily burden our effort here, considering that our focus is not on surfzone waves. Anyway, discrepancies at gage S24 will not affect results at section S18, where the cylindrical obstacle is located in the second set of experiments, which is downslope of S20, where the agreement between numerical and experimental results is very good.

In this respect, Fig. 5 shows average wave elevation computed at gage S18, with and without the bottom obstacle. The effect of the obstacle is quite small and only translates into a 6% maximum change in wave elevation.

Near bottom particle velocities

Fig. 6 shows phase-averaged horizontal (u) and vertical (w) velocities computed in sections S20, S22 and S24, at 0.1 m above the bottom, without the obstacle. The horizontal velocity is compared with ADV

11

measurements. The agreement is quite good, even at section S24. Hence, errors on wave crest shape (Fig. 4c) do not seem to affect predicted near bottom velocities to the same extent. Comparing Figs. 4 and 6, we see that horizontal velocities directly reflect wave asymmetry with, as expected, larger onshore velocities under crests and smaller offhore velocities under troughs. Vertical velocities are out of phase with horizontal velocities and are also strongly asymmetric, with much larger upward velocities, preceding crests, than downward velocities, preceding troughs. Such velocity patterns are directly related to observed onshore sediment transport (migrating ripples; Voropayev et al., 2003b).

More specifically, the maximum tangential velocity u_{bs}^{max} on the bottom is the key wave forcing parameter for sediment suspension, through the effect of the wave-induced maximum bottom shear stress τ_{bs}^{max}, e.g., as calculated by Eq. (8). Moreover, Stokes drift, i.e., the mean mass transport current, whose strength near the bottom can be estimated by the difference between maximum (onshore) u_{bs}^{max} and minimum (offshore) u_{bs}^{min} bottom velocities, is the main forcing for mean onshore sediment transport and ripple migration observed in experiments. Fig. 7, for instance, shows instantaneous tangential bottom velocity, computed in the NWT every 20 time steps from $t = 45.14$ s to 47.20 s, which covers a full wave period. Maximum and minimum velocity envelopes are plotted in the figure for $x \leq x_a$, which marks the beginning of the numerical AB in the NWT. For the incident wave at $x = 0$, bottom velocities are symmetrical, oscillating between -0.25 m/s and +0.25 m/s. As waves shoal up the slope ($x > 0$), as expected, bottom velocity increases but, for a given x location, maximum bottom velocities become increasingly larger than minimum velocities, in absolute value. Maximum velocity predicted by linear wave theory (LWT; Eqs. (12) to (15)), is also plotted on Fig. 7 (with $m_o = 1.163$ and $\theta = 2.39$ deg.). While the maximum (onshore) velocity seems quite well predicted by LWT, the minimum (offhsore) velocity is increasingly overpredicted by LWT, as a result of increasing flow asymmetry, as waves shoal up.

The good prediction provided by LWT for the maximum bottom velocity can be explained by the work of Grilli (1998). For nonlinear waves, shoaling wave heights computed in the NWT or observed in experiments are larger than predicted by LWT : $H = H_o \sqrt{m_o/m}$ (Eqs. (14) and (15)) and, due to amplitude dispersion effects, nonlinear wave celerities are also larger than predicted by the linear dispersion Eq. (13). In Eq. (12),

we readily see from the definition : $c = \omega/k$, that $u_{bs}^{max} \propto gH/c$, which is proportional to wave steepness. Comparing the nonlinear wave steepness computed in the NWT to the linear value, for a range of incident wave steepness, during shoaling up to the breaking point, Grilli (1998) found maximum differences of 10% and concluded that the nonlinear effects mentioned above, of both larger H and larger c, approximately compensated each other in the H/c ratio. Fig. 8, which is based on results in Fig. 7, gives an additional confirmation of this conclusion for the present computations, which were performed for fairly steep incident waves ($kH_o = 0.18$ at the wavemaker). We see that LWT overpredicts maximum bottom velocities by 10% or less but the minimum velocities are increasingly overpredicted, as waves shoal up, by up to 35%. Maximum velocity is thus fairly well predicted by LWT, whereas minimum velocity is not. The latter is clearly related to wave asymmetry and could only be correctly parameterized by first performing a full analysis of wave asymmetry as a function of incident wave parameters.

Velocity field around the cylindrical obstacle

Computations are repeated with the cylindrical obstacle semi-buried on the bottom of section S18 (Fig. 1). Wave and NWT parameters are similar to those used above.

As shown in Fig. 5, free surface elevations are not significantly affected by the presence of the cylinder. Hence, the calibration of the NWT presented above also applies to this case. To quantify the effect of the obstacle on the flow and, possibly, on induced sediment transport, internal velocities, both instantaneous and phase-averaged, are computed at points located around the obstacle and compared to experiments.

Fig. 9 shows two typical views of instantaneous velocity vectors computed above and near the cylindrical obstacle, when a wave crest is about to pass over it ($t = 31.88$ s) and when a wave trough has just passed by ($t = 33.75$ s). Incident waves are fairly long at this location, with a ratio of length over depth larger than 16. In the leftward figure, both in front and behind the cylinder, we see markedly larger horizontal velocities u near the free surface than closer to the bottom. For such long waves, this is clearly due to the large nonlinearity (wave height is about 50% of the local depth and maximum particle velocities at the surface reach about 0.7 m/s or about 27% of the local wave celerity $c = 2.6$ m/s). In the rightward figure,

13

u is fairly uniform over depth away from the cylinder, as expected for a long wave. Moving closer to the obstacle, we see in both figures a large increase in horizontal velocity, right above the cylinder. This could be expected from simple potential flow computations of a circular cylinder in a uniform flow, which would predict u on the cylinder top, up to twice the free stream velocity. On the cylinder sides, we also see the effect of the cylinder on vertical velocities w, with the flow being forced to follow the cylinder boundary and thus being forced upward on the upstream side, and downward on the downstream side, with respect to the flow direction (i.e., sign of u).

Fig. 10 shows locations for 5 points around the cylinder, where phase-averaged velocities u and w are calculated. In Figs. 11 and 12, these are compared both with a reference velocity, calculated at 0.1 m above the bottom in section S18 without the cylinder (point R), and with experimental results. We see that computations of both u and w agree well with experiments for point 1 (0.001 m above the cylinder). As expected, $|u|$ increases by a factor of 2 in both directions of the flow, as compared to results without the obstacle (R). This effect, however, is quite local as $|u|$ is not so significantly affected at points 2 and 5, one radius above the bottom and half a radius in front or behind the cylinder, where computations agree quite well with experriments. As expected, w is very small at point 1 due to the no-flow condition on the cylinder. At points 3 and 4, one diameter over the bottom and one radius plus 0.001 m above the cylinder, respectively, results of computations and experiments agree well for both u and w. Here, $|u|$ increases by about 50 percent as compared to (R), and w experiences much more variations than u (and even more in experiments), due to the presence of the obstacle. At points 2 and 5, in computations, w shows the largest deviation with respect to (R), as the flow is forced to move up or down the cylinder, depending on its direction. Here, however, we see larger discrepancies between computations and experiments. These could be explained by flow separation and vortex shedding in experiments, on the downstream side of the cylinder with respect to the sign of u. Thus, at point 2, the relative increase in measured $|w|$, with respect to computations, is larger under wave troughs, when $u < 0$ and $w < 0$, and at point 5, it is larger under the crests. In addition, due to the larger $|u|$ under crests (and thus vortex shedding), the increase in $|w|$ is larger at point 5 than at point 2. All of these effects should enhance sediment suspension and transport in the vicinity of the cylinder.

Conclusions

We numerically and experimentally studied the propagation of long periodic waves over semi-buried cylindrical objects in sandy bottom. After minor calibrations consisting in adjusting parameters of the wavemaker, the absorbing beach, and the bottom friction dissipation, the comparison between computed and experimental results is quite good over the sandy slope, for both wave elevations and near bottom velocities, even close to breaking. [Note, the effect of bottom friction on wave shape, although enhanced by the rippled bed, only translates in the model in a few percent changes, as compared to the case without friction; hence, this is still quite a small effect.] The effect of the cylinder on wave elevation is very small. Significant changes, however, are observed for particle velocites, up to one radius away from the cylinder. Computed and measured velocities agree quite well, except for the vertical velocity in front and behind the cylinder, where measured $|w|$ values increase, likely due to vortex shedding, a phenomenon which can not modeled in potential flow computations. Overall, absolute values of the velocity are increased around the cylinder, which will affect both sediment suspension and transport. This is well observed in laboratory experiments (Voropayev et al., 2003a).

Based on these results, at a short distance away from the cylinder (say $> 2r$; particularly above and upstream, with respect to the sign of u; see also Fig. 9), the potential flow model should accurately predict velocities. The model can thus be used to provide background wave fields around the buried object, to both study sediment transport and perform more refined modeling of the flow around the obstacle, e.g., based on solving Navier-Stokes (NS) equations and using a sediment transport model. This will be done in future work.
